

The Riemann Hypothesis: Distribution of Prime Numbers and the Zeros of the Zeta Function

The distribution of prime numbers is one of the oldest and deepest problems in mathematics. Gauss and Legendre conjectured around 1800 that the number of primes up to x , denoted $\pi(x)$, behaves asymptotically as $x/\ln x$ [5]. This result, known as the Prime Number Theorem, was proved in 1896 by Hadamard and de la Vallée Poussin [5]. In 1859, Riemann introduced the zeta function [4], defined for $\Re(s) > 1$ by

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s} = \prod_{p \text{ prime}} \frac{1}{1 - p^{-s}}$$

and extended it to the whole complex plane by analytic continuation [4]. Riemann observed that $\zeta(s)$ vanishes at all negative even integers (trivial zeros), and that all remaining non-trivial zeros lie in the strip $0 < \Re(s) < 1$ [4]. He conjectured that all non-trivial zeros lie exactly on the critical line $\Re(s) = 1/2$ [4]. This conjecture, known as the Riemann Hypothesis [2], remains unproved after more than 160 years and is listed as one of the seven Millennium Prize Problems [2].

Hardy proved in 1914 that infinitely many zeros lie on the critical line [5]. This was later strengthened by Hardy and Littlewood (1921), who obtained quantitative estimates [5]. Selberg (1942) showed that a positive proportion of zeros lie on the critical line [5], and Conrey pushed this proportion [3] above two fifths, which remains the best known result to this day. On the computational side, Odlyzko and Schonhage [6] developed fast algorithms based on the Riemann-Siegel formula [4] to evaluate $\zeta(s)$ efficiently at many points, enabling large-scale numerical verification. These computations have confirmed that the first 10^{22} zeros all lie on the critical line [6], providing strong empirical support for the hypothesis. Another major direction connects the zeros of $\zeta(s)$ to quantum mechanics and random matrix theory [1]: the statistical spacing between consecutive zeros follows the same distribution as eigenvalues of random unitary matrices [1]. This unexpected connection, supported by the numerical work of Odlyzko, suggests that the zeros might be eigenvalues of some unknown Hermitian operator [1]. This is known as the Hilbert-Pólya conjecture and has inspired a rich interdisciplinary research program at the intersection of number theory and mathematical physics [1].

Despite these advances, the Riemann Hypothesis [2] remains one of the most important open problems in mathematics. Several directions are actively pursued. First, the proportion of zeros proven to lie on the critical line is still far from 100% [3], and pushing this bound further requires new analytic tools such as improved mollifiers and mean-value estimates for $\zeta(s)$ [5]. Second, current zero-free regions are far from the critical line [5], and stronger results would yield better error terms in the Prime Number Theorem unconditionally. Third, the Hilbert-Pólya conjecture remains open: no Hermitian operator [1] whose eigenvalues are the imaginary parts of the zeros has been constructed rigorously. A deeper understanding of the analytic properties of $\zeta(s)$ [4] and more powerful tools from analytic number theory [5] are needed to make further progress toward a proof.
